The type of interpolation to be used depends on several factors:

1) What data are available: The quaternion at each time step; the body rotational rates?
2) What is/is not to be preserved at sampling points.
3) What the expected vehicle behavior is: Are rotational rates high relative to sampling rate?

- note on notation: i's refer to times; j's refer to elements of quaternion, vector, etc.; k's refer to polynomial coefficients.

Quaternion definition:

## Euler's theorem:

The rotational relationship between any two coordinate frames can be described by an axis of rotation that is fixed in both coordinate frames and a total rotation angle.

$$
\begin{array}{ll}
\text { Rotation axis: } & \mathbf{e}=\mathrm{e}_{1} \mathrm{e}_{2} \mathrm{e}_{3} \quad \text { (assumed unit magnitude) } \\
\text { Rotation angle: } & \phi \\
\qquad \mathrm{Q}=\quad & \mathrm{q}_{1}=\mathrm{e}_{1} \sin (\phi / 2) \\
& \mathrm{q}_{2}=\mathrm{e}_{2} \sin (\phi / 2) \\
& \mathrm{q}_{3}=\mathrm{e}_{3} \sin (\phi / 2) \\
& \mathrm{q}_{4}=\cos (\phi / 2)
\end{array}
$$

Interpolation of Quaternion elements
Given data: time ordered sets of

1) attitude described by the quaternion from reference frame to body frame, $\mathrm{Q}\left(\mathrm{t}_{\mathrm{i}}\right)$, and
2) rotational rate in the body frame, $\omega\left(\mathrm{t}_{\mathrm{i}}\right)=\omega_{1} \omega_{2} \omega_{3}$

## Two Point Methods:

using normalized time: $\mathrm{t}_{\mathrm{N}}=\left(\mathrm{t}-\mathrm{t}_{\mathrm{i}}\right) /\left(\mathrm{t}_{\mathrm{i}+1}-\mathrm{t}_{\mathrm{i}}\right), \quad \mathrm{t}_{\mathrm{i}} \leq \mathrm{t} \leq \mathrm{t}_{\mathrm{i}+1}$

## Linear:

$$
\begin{aligned}
& \mathrm{Q}(\mathrm{t})=\mathrm{Q}\left(\mathrm{t}_{\mathrm{i}}\right)+\mathrm{t}_{\mathrm{N}} *\left(\mathrm{Q}\left(\mathrm{t}_{\mathrm{i}+1}\right)-\mathrm{Q}\left(\mathrm{t}_{\mathrm{i}}\right)\right) \\
& \text { or } \\
& \quad \mathrm{q}_{1}(\mathrm{t})=\mathrm{q}_{1}\left(\mathrm{t}_{\mathrm{i}}\right)+\mathrm{t}_{\mathrm{N}} *\left(\mathrm{q}_{1}\left(\mathrm{t}_{\mathrm{i}+1}\right)-\mathrm{q}_{1}\left(\mathrm{t}_{\mathrm{i}}\right)\right)
\end{aligned}
$$

$$
\begin{aligned}
& \mathrm{q}_{2}(\mathrm{t})=\mathrm{q}_{2}\left(\mathrm{t}_{\mathrm{i}}\right)+\mathrm{t}_{\mathrm{N}} *\left(\mathrm{q}_{2}\left(\mathrm{t}_{\mathrm{i}+1}\right)-\mathrm{q}_{2}\left(\mathrm{t}_{\mathrm{i}}\right)\right) \\
& \mathrm{q}_{3}(\mathrm{t})=\mathrm{q}_{3}\left(\mathrm{t}_{\mathrm{i}}\right)+\mathrm{t}_{\mathrm{N}} *\left(\mathrm{q}_{3}\left(\mathrm{t}_{\mathrm{i}+1}\right)-\mathrm{q}_{3}\left(\mathrm{t}_{\mathrm{i}}\right)\right) \\
& \mathrm{q}_{4}(\mathrm{t})=\mathrm{q}_{4}\left(\mathrm{t}_{\mathrm{i}}\right)+\mathrm{t}_{\mathrm{N}} *\left(\mathrm{q}_{4}\left(\mathrm{t}_{\mathrm{i}+1}\right)-\mathrm{q}_{4}\left(\mathrm{t}_{\mathrm{i}}\right)\right)
\end{aligned}
$$

Advantages:
Simple to implement
Disadvantages:
Will have instantaneous rate changes at sampling points.
$3^{\text {rd }}$ order interpolation:
Assume:

$$
\begin{aligned}
& q_{1}(t)=a_{10}+a_{11} t_{N}+a_{12} t_{N}^{2}+a_{13} t_{N}^{3} \\
& q_{2}(t)=a_{20}+a_{21} t_{N}+a_{22} t_{N}^{2}+a_{23} t_{N}{ }^{3} \\
& \mathrm{q}_{3}(\mathrm{t})=\mathrm{a}_{30}+\mathrm{a}_{31} \mathrm{t}_{\mathrm{N}}+\mathrm{a}_{32} \mathrm{t}_{\mathrm{N}}^{2}+\mathrm{a}_{33} \mathrm{t}_{\mathrm{N}}{ }^{3} \\
& q_{4}(t)=a_{40}+a_{41} t_{N}+a_{42} t_{N}^{2}+a_{43} t_{N}{ }^{3}
\end{aligned}
$$

to solve for the elements of the a matrix:

$$
\text { setting } t_{\mathrm{N}}=0.0
$$

a) $\quad \mathrm{q}_{\mathrm{j}}\left(\mathrm{t}_{\mathrm{i}}\right)=\mathrm{a}_{\mathrm{j} 0}$

$$
\text { setting } \mathrm{t}_{\mathrm{N}}=1.0
$$

b) $\quad \mathrm{q}_{\mathrm{j}}\left(\mathrm{t}_{2}\right)=\sum_{\mathrm{k}=0,3} \mathrm{a}_{\mathrm{jk}}$
using

$$
\dot{\mathrm{Q}}=1 / 2 \mathrm{Q} \omega
$$

setting $\mathrm{t}_{\mathrm{N}}=0.0$
c) $\quad \dot{\mathrm{q}}_{1}\left(\mathrm{t}_{\mathrm{i}}\right)=\mathrm{a}_{11}=1 / 2\left(\mathrm{q}_{2}\left(\mathrm{t}_{\mathrm{i}}\right) \omega_{3}\left(\mathrm{t}_{\mathrm{i}}\right)-\mathrm{q}_{3}\left(\mathrm{t}_{\mathrm{i}}\right) \omega_{2}\left(\mathrm{t}_{\mathrm{i}}\right)+\mathrm{q}_{4}\left(\mathrm{t}_{\mathrm{i}}\right) \omega_{1}\left(\mathrm{t}_{\mathrm{i}}\right)\right)$ (similarly for $\dot{\mathrm{q}}_{2}\left(\mathrm{t}_{\mathrm{i}}\right), \dot{\mathrm{q}}_{3}\left(\mathrm{t}_{\mathrm{i}}\right), \dot{\mathrm{q}}_{4}\left(\mathrm{t}_{\mathrm{i}}\right)$ )
setting $\mathrm{t}_{\mathrm{N}}=1.0$
d) $\underset{\mathrm{i}+1)}{ } \quad \dot{\mathrm{q}}_{1}\left(\mathrm{t}_{\mathrm{i}+1}\right)=\underset{\mathrm{j}=0,3}{ } \mathrm{ja}_{1 \mathrm{j}}=1 / 2\left(\mathrm{q}_{2}\left(\mathrm{t}_{\mathrm{i}+1}\right) \omega_{3}\left(\mathrm{t}_{\mathrm{i}+1}\right)-\mathrm{q}_{3}\left(\mathrm{t}_{\mathrm{i}+1}\right) \omega_{2}\left(\mathrm{t}_{\mathrm{i}+1}\right)+\mathrm{q}_{4}\left(\mathrm{t}_{\mathrm{i}+1}\right) \omega_{1}(\mathrm{t}\right.$ (similarly for $\mathrm{q}_{2}\left(\mathrm{t}_{\mathrm{i}+1}\right), \mathrm{q}_{3}\left(\mathrm{t}_{\mathrm{i}+1}\right), \mathrm{q}_{4}\left(\mathrm{t}_{\mathrm{i}+1}\right)$ )

Equations a-d provide four equations for each of the quaternion elements from which the four coefficients for each element can be derived.

Advantages:
Preserves both postion and rate at end points - no sudden rate discontinuity.
Disadvantages:

More complex to implement.

## Higher Order Interpolation

$\mathrm{N}+1$ things (position, rate, acceleration, etc. at a point) can be preserved, where N is the order of the polynomial.

If order < number of points, position will not be preserved at sampling points.
The higher the order, the greater risk of unacceptable behavior; there may be peaks/valleys corresponding to the order used.

## Other types of Interpolation

Interpolation between attitudes can also be performed by calculating the Eigen rotation axis and the total angle between the two attitudes and calculating a delta quaternion from the first using a portion of the angle between at each step. The angle can be a linear or non linear function of time,
$\mathbf{e}=e_{1} \quad e_{2} \quad e_{3} \quad$ rotation axis $\phi(\mathrm{t})=\phi_{\mathrm{T}} * \mathrm{f}(\mathrm{t}) \quad$ rotation angle at time t

Where: $\quad f(t) \quad$ a function of time, $0.0 \leq f(t) \leq 1.0$
$\phi_{\mathrm{T}} \quad$ total angle between two attitudes
then
$\mathrm{Q}_{\Delta}=\mathrm{e}_{1} \sin (\phi / 2) \mathrm{e}_{2} \sin (\phi / 2) \mathrm{e}_{3} \sin (\phi / 2) \cos (\phi / 2)$
and
$\mathrm{Q}(\mathrm{t})=\mathrm{Q} \mathrm{Q}_{\Delta}$
This is called a "slerp" - spherical linear interpolation - in several literature sources, notably the paper by Ken Shoemake (although, if a non-linear time function is used, this is no longer linear). I used this method to generate attitude maneuvers on another program for the last decade or so.

This formulation ignores rotational rates and their discontinuities at the endpoints; we can devise methods of smoothing to deal with this, if necessary.

## For All Interpolation Schemes:

If rotation rate is larger than $\pi / \mathrm{T}_{\mathrm{s}}$, where $\mathrm{T}_{\mathrm{s}}$ is the sampling interval, interpolation cannot be done unambiguously, given position only data. If rates are given, assumptions about intervening behavior can be made and interpolation performed.

## Quaternion Integration:

If the inertia matrix, $\mathbf{I}$, is available:

1) calculate rotation rate derivatives in the body frame from:
$\dot{\omega}=\mathbf{I}^{-1}(\boldsymbol{\tau}-\boldsymbol{\omega} \mathbf{X I} \boldsymbol{\omega}) \quad$ where $\boldsymbol{\tau}=$ external torque
integrate to generate $\omega$
$\omega=\int \omega \mathrm{dt}$
2) Calculate quaternion derivatives from:
(after appending " 0 " (a zero) to $\omega$ to make it a fourtuple and compatible with quaternion multiplication)

$$
\dot{\mathrm{Q}}=1 / 2 \mathrm{Q} \omega
$$

$$
\mathrm{Q}=\int \dot{\mathrm{Q}} \mathrm{dt}
$$
